

Indoor Air Quality Impacts of a Woodstove Exchange Program in Washington County, Oregon

Master's Thesis Defense

6/1/2020

Matt Survilo

- As of 2015 , 11.6 million homes used wood as their primary or secondary fuel source.¹
- Wood stoves used to heat homes are often old and inefficient² . these stoves generate particulate matter (PM) that lead to degraded air quality.
- Strong evidence exists that shows indoor levels of PM can adversely affect human health.³

References available at end of presentation.

Washington County

- Washington County often ranks as one of the healthiest counties in Oregon.
- Winter-time air quality is some of the worst in the state.
- 1/3 of homes use these old stoves for heating which is a major source of winter-time air pollution.
- Washington County has had $PM_{2.5}$ levels that put the county at risk for violating the federal Clean Air Act.

Wood Stove Exchange Program (WSEP)

- Washington county created an incentive program to help homeowners replace old wood stoves
- Since launching in 2016, 390 stove exchanges have occurred.
- The WSEP estimates this has resulted in a 28 ton reduction in particulate matter and 164 ton reduction of other air pollutants. (CO, VOCs etc)

Project Overview

- We coupled with Washington County to monitor air quality before and after a wood stove exchange.
- Investigated correlation of building weatherization (i.e. airtightness) with indoor and household outdoor air pollution levels.
- Attempted to leverage data to identify wood stove $PM_{2.5}$ source strengths.

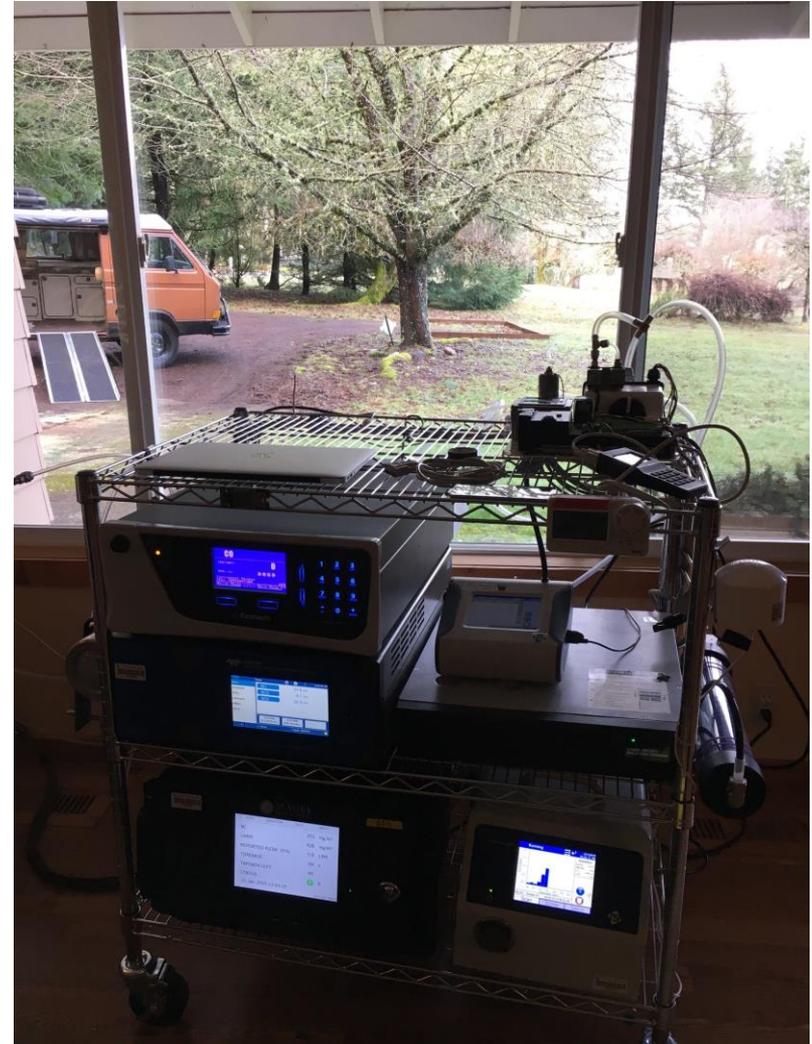

1. Will the WSE effect **indoor** levels of air pollution?
 2. Will the WSE effect **household outdoor** levels of air pollution?
 3. Are periods of **woodstove operation** associated with elevated levels of pollution, inside and around the home?
 4. Are **building weatherization** (i.e. airtightness) metrics associated with indoor or household outdoor air pollution levels?
-

Recruitment of households

- Two requirements for study inclusion
 - Household has an existing woodstove or fireplace
 - New heating source must be a woodstove or ductless heat pump
- Participants were offered a financial incentive to participate in the study.
 - \$50 for basic monitoring
 - \$200 for enhanced monitoring

Basic air quality monitoring instrumentation

Constituent	Method	Device	Time-resolution	Deployment
PM2.5, PM10	Low cost, light-scattering sensor	PurpleAir PA-II SD	Real-time, <5 min	Entire monitoring period
Stove operation	Temperature sensor/logger	Geocene Dot	Real-time, <5 min	Entire monitoring period
Building airtightness	Whole-house blower door test	Minneapolis Blower Door	Once per home	Once per home
Carbon dioxide	Non-dispersive infrared sensor	Onset MX1102	5 min	Entire monitoring period

- Low cost light scattering sensor.
- $PM_{2.5}$ and PM_{10}
- Counts particles in size bins from 0.3 – 10 μm
- Often particle counts are within a factor of two compared to research grade equipment.

- High temperature sensor and data logger.
- Allowed for AQ data to be filtered for periods when stoves were active.
- Threshold temperatures were chosen for each household, above which stove use was apparent

- Used to conduct a multi-point blower door test.
- Data enables estimation of pressure-flow relationships for each household.
- Also allows for calculation of estimated leakage area.

Methods: CO2 Monitor

- Monitors were setup outside the home and in the common area of the home.

Enhanced air quality monitoring instrumentation

Constituent	Method	Device	Time-resolution	Deployment
Black carbon	5-wavelength aethalometer	Magee Aethalometer	Real-time, 5 minute resolution due to switching valve	3 days pre exchange, 3 days post
Brown carbon (UVPM)	5-wavelength aethalometer	Magee Aethalometer	Real-time, 5 minute resolution due to switching valve	3 days pre exchange, 3 days post
Carbon monoxide	Non-dispersive infrared with filter correlation	Ecotech Serinus 30 CO monitor	Real-time, 5 minute resolution due to switching valve	3 days pre exchange, 3 days post

- Black carbon measured by light attenuation at 880nm.
 - Indicates fossil fuel burning
- Brown carbon proxy (UVPM) measured by attenuation at 370nm.
 - Indicates biomass combustion

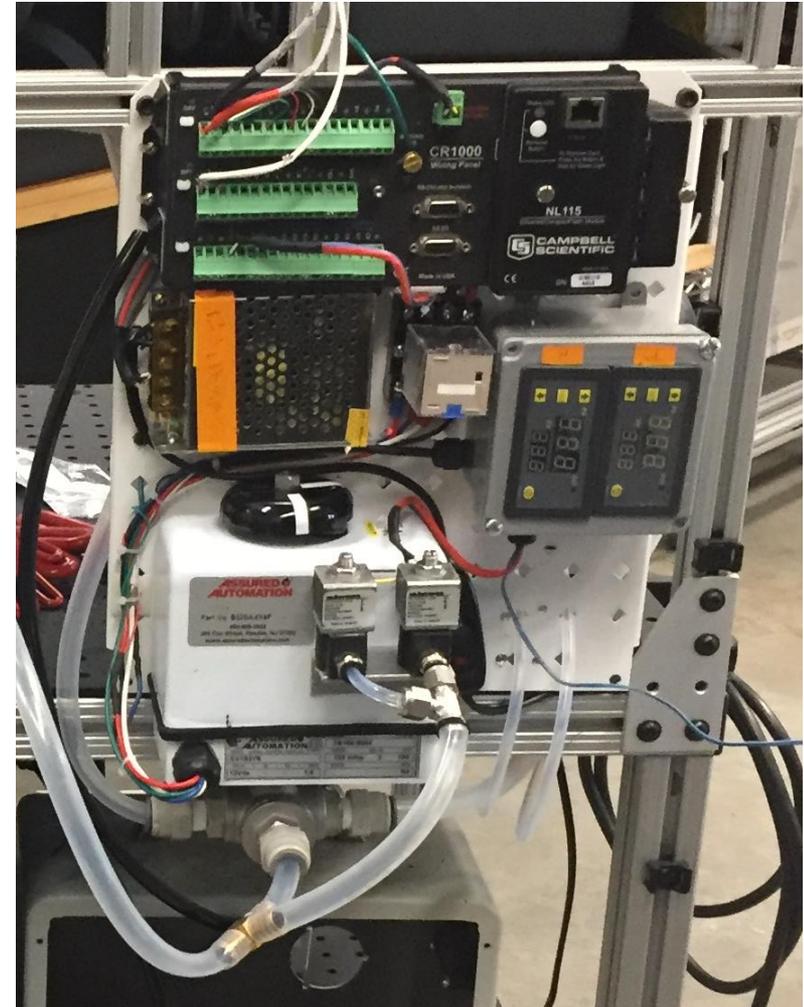

Carbon monoxide

- Uses a nondispersive infrared sensor to detect CO
- Analyzer was factory calibrated prior to field deployment.

- One set of instruments can sample both inside and outside if the sampling port is switched.
- A switching valve for particle and gas phase constituents was developed.
- Location duration was 5 minutes.

Challenges

- Presumably more efficient woodstoves emit few air pollutants.
- In field studies many variables cannot be controlled, and the **households** in this study are engaging in behaviors and **activities that are variant in time**.
- Additionally regional **ambient background levels of air pollution fluctuate** on diurnal, weekly, and seasonal time-scales.
- A variety of empirical approaches were taken here as a first step in developing an understanding of the WSEs impact on local and indoor air quality.

Local Outdoor

- Pre and post exchange levels of outdoor $PM_{2.5}$ were measured directly using a PurpleAir sensor attached to the outside of the home.
- This comparison should be interpreted cautiously, as background levels of air pollution changed over the course of the study for many deployments.

Indoor

- Similarly absolute levels of $PM_{2.5}$ pre and post exchange inside the home were measured.
- From the perspective of exposure, this metric is a direct representation of whether the woodstove exchange program reduced exposures to air pollution.

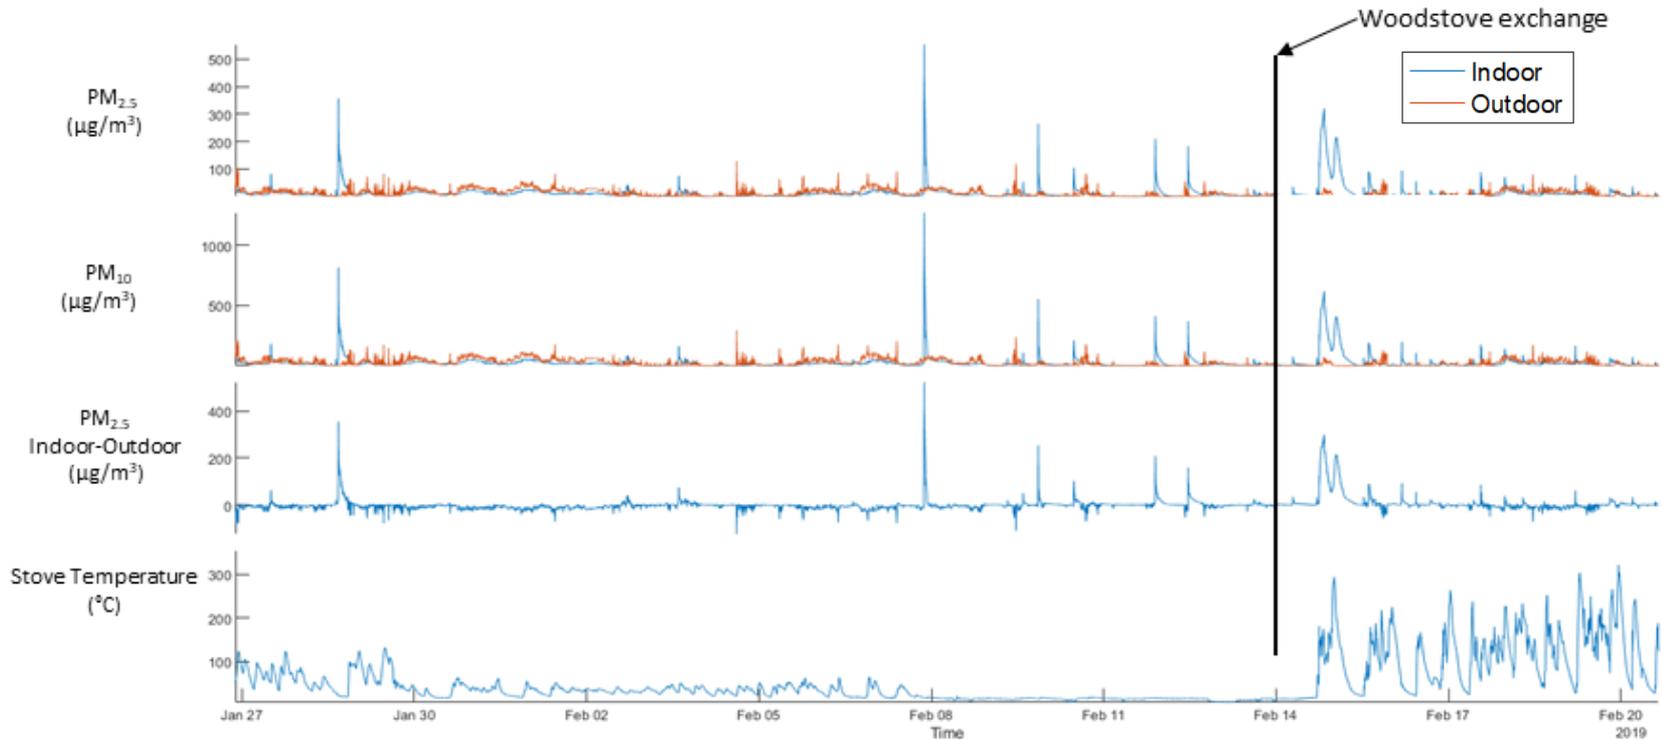

Comparison

- Comparing indoor and outdoor levels of pollution may be the most effective method in determining the effect of the WSE
- Indoor-outdoor comparison allow for effect of background pollution changes to be minimized

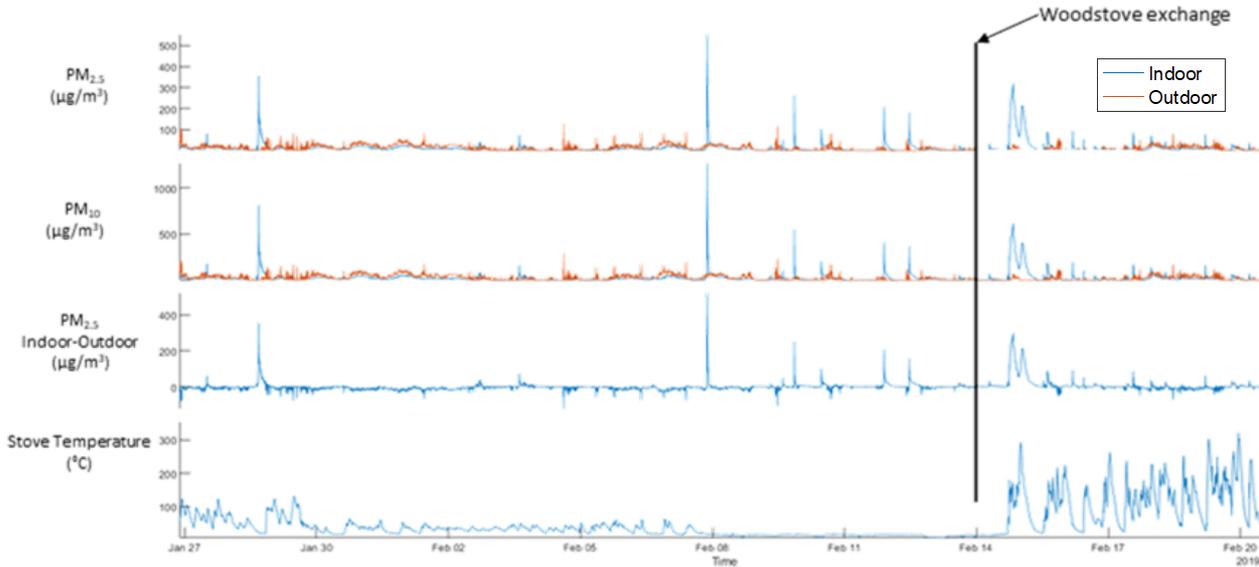

$$\Delta C = C_{indoor} - C_{outdoor}$$

Bulk statistical analysis

Is data normally distributed?

No

Are differences between pre and post exchange median values statistically significant?

For the non-parametric data a sign test was conducted for all pre-post differences.

The differences observed were not statistically significant.

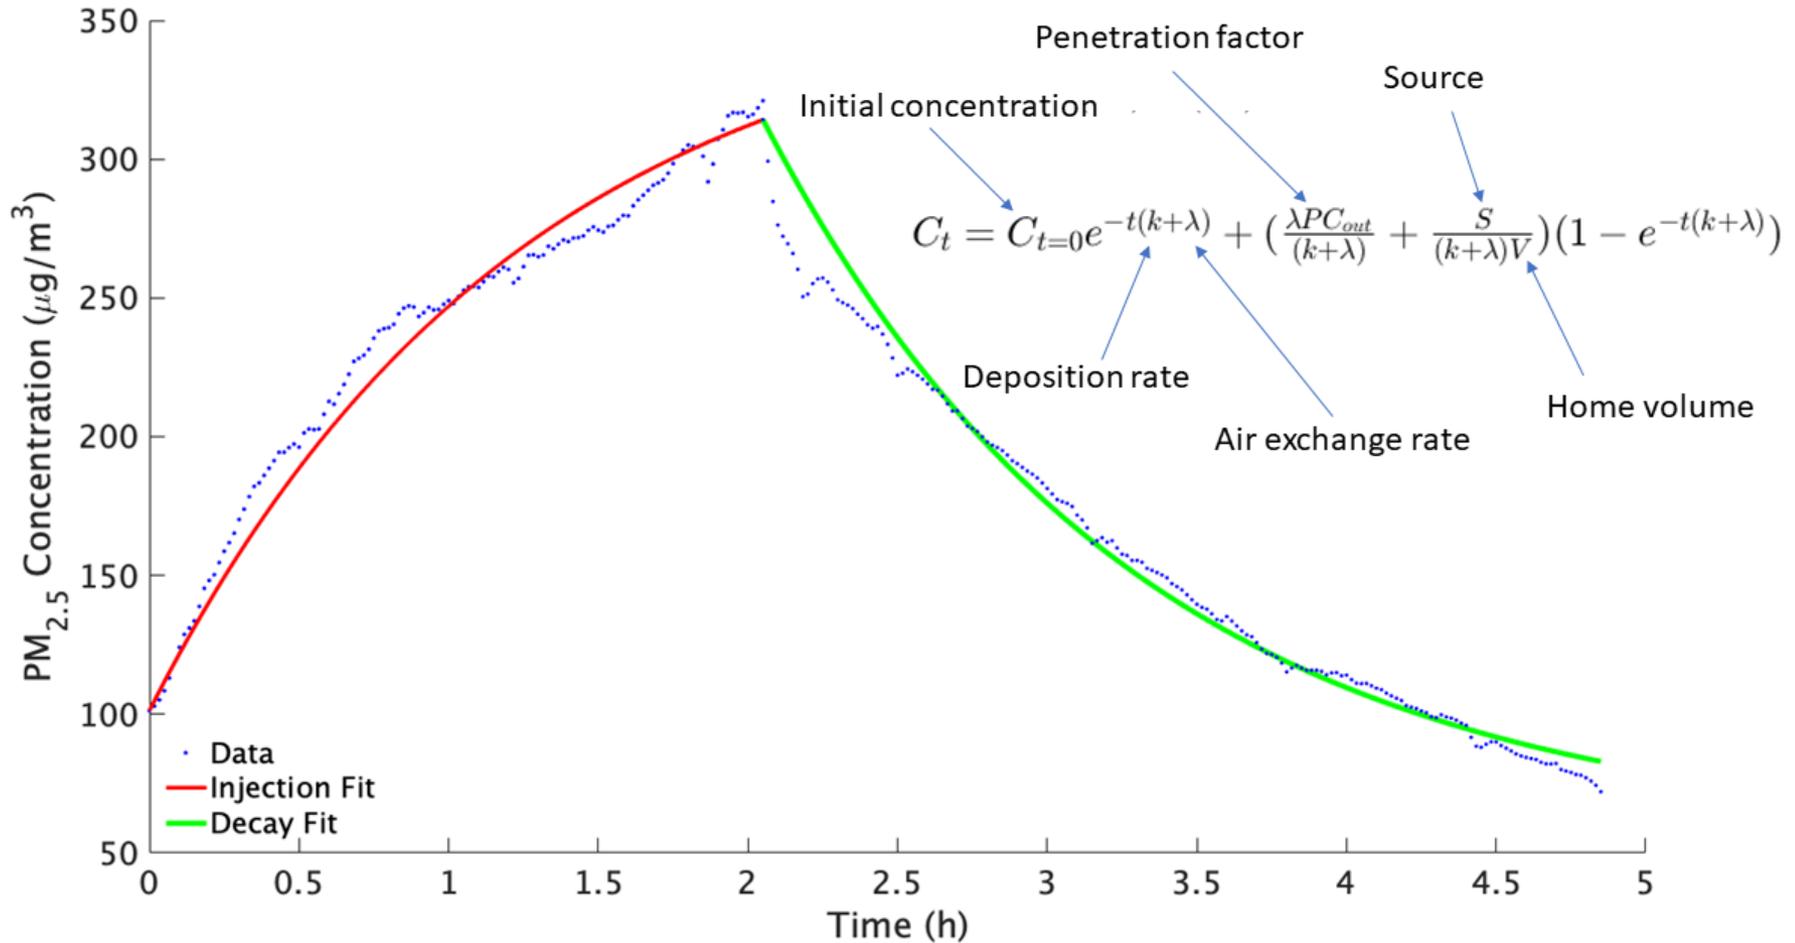

Stove PM_{2.5} source strength analysis

- 13 of 17 homes with data available exhibited large transient PM_{2.5} peaks associated with the first burn of the new stove.
- This discovery was an opportunity to investigate particle source and sink mechanisms.
- Applied mass-balance principles to the substantial elevation and subsequent decay of indoor PM_{2.5}

$$\frac{dC_{\text{in}}}{dt} = -\lambda C_{\text{in}} + \lambda C_{\text{out}} + S/V$$

Correlation between normalized leakage area (NLA) and changes in $PM_{2.5}$

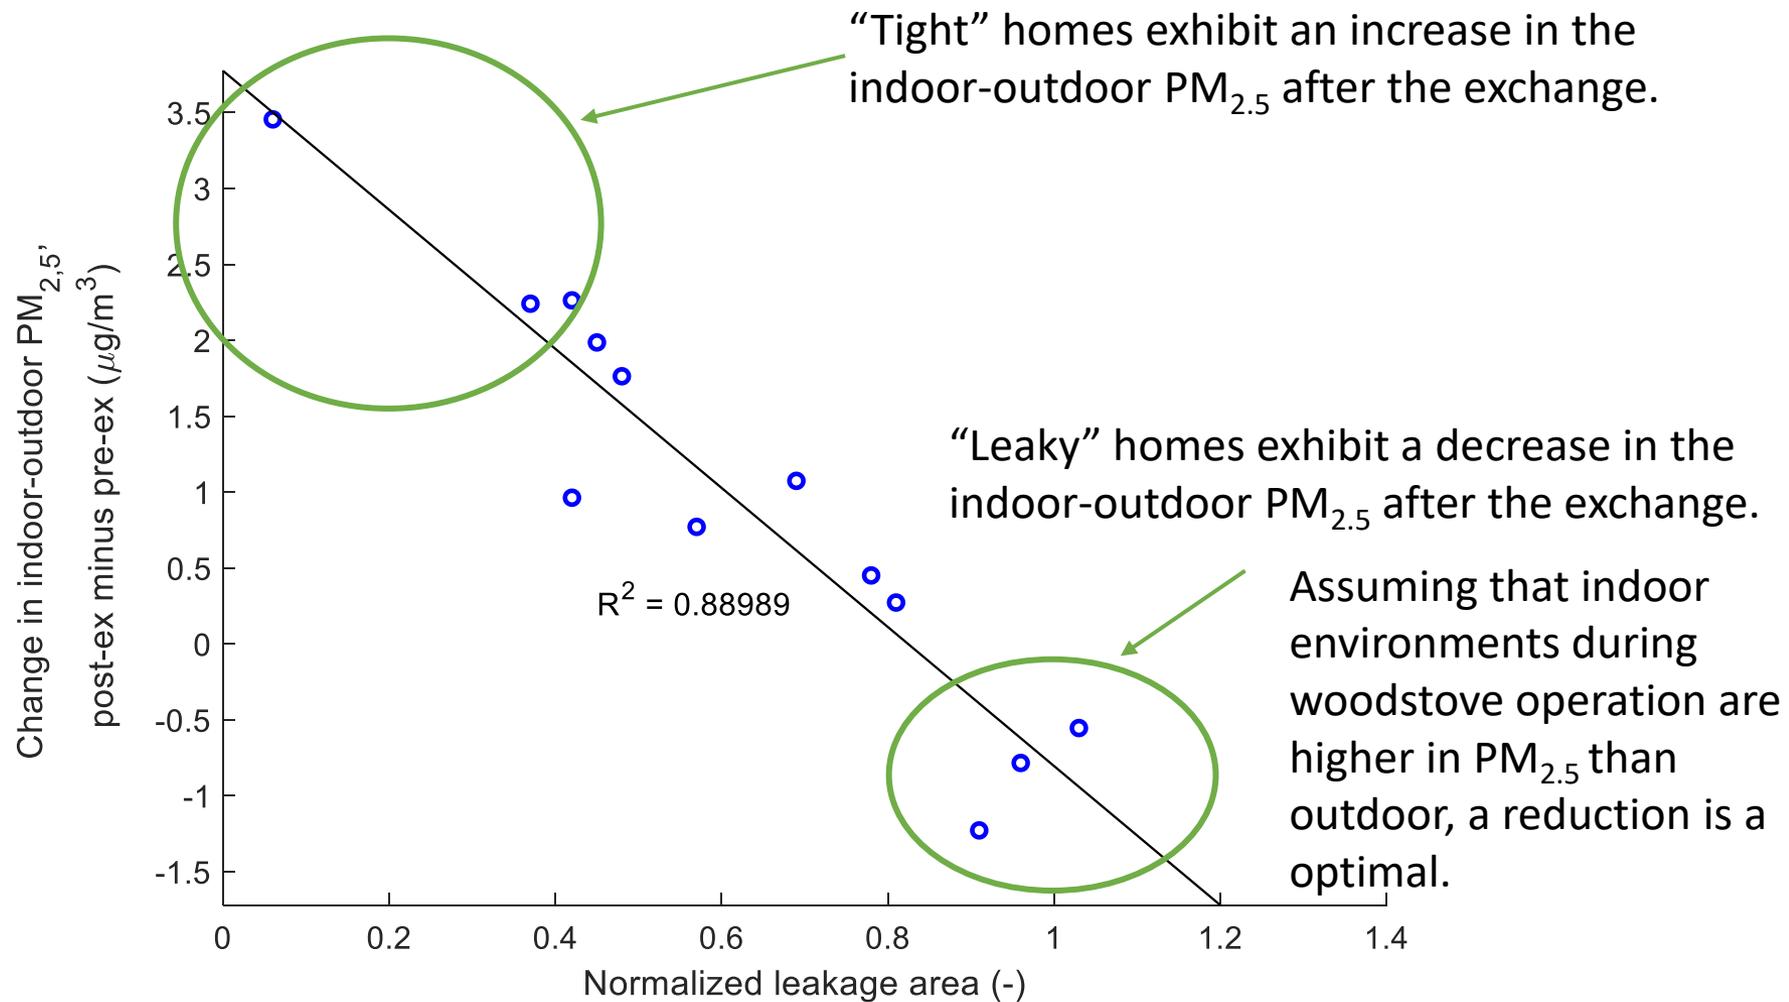

NLA is derived from the estimated leakage area (ELA) which is analogous to the cross-sectional area of an orifice that would yield the same leakage flow rate as if the building were subjected to a 4 Pa pressure difference across the building envelope.

Indoor – Outdoor $PM_{2.5}$ ($\Delta C_{PM_{2.5}}$) is a useful metric because it normalizes the indoor concentration to the ambient outdoor environment.

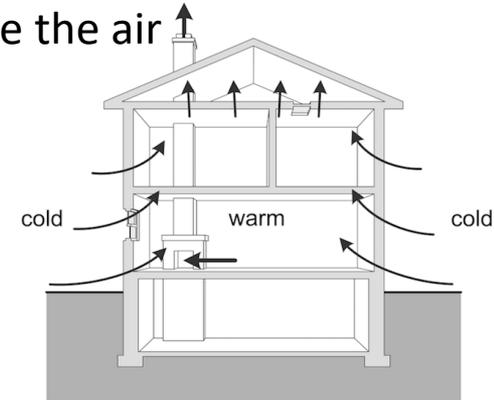

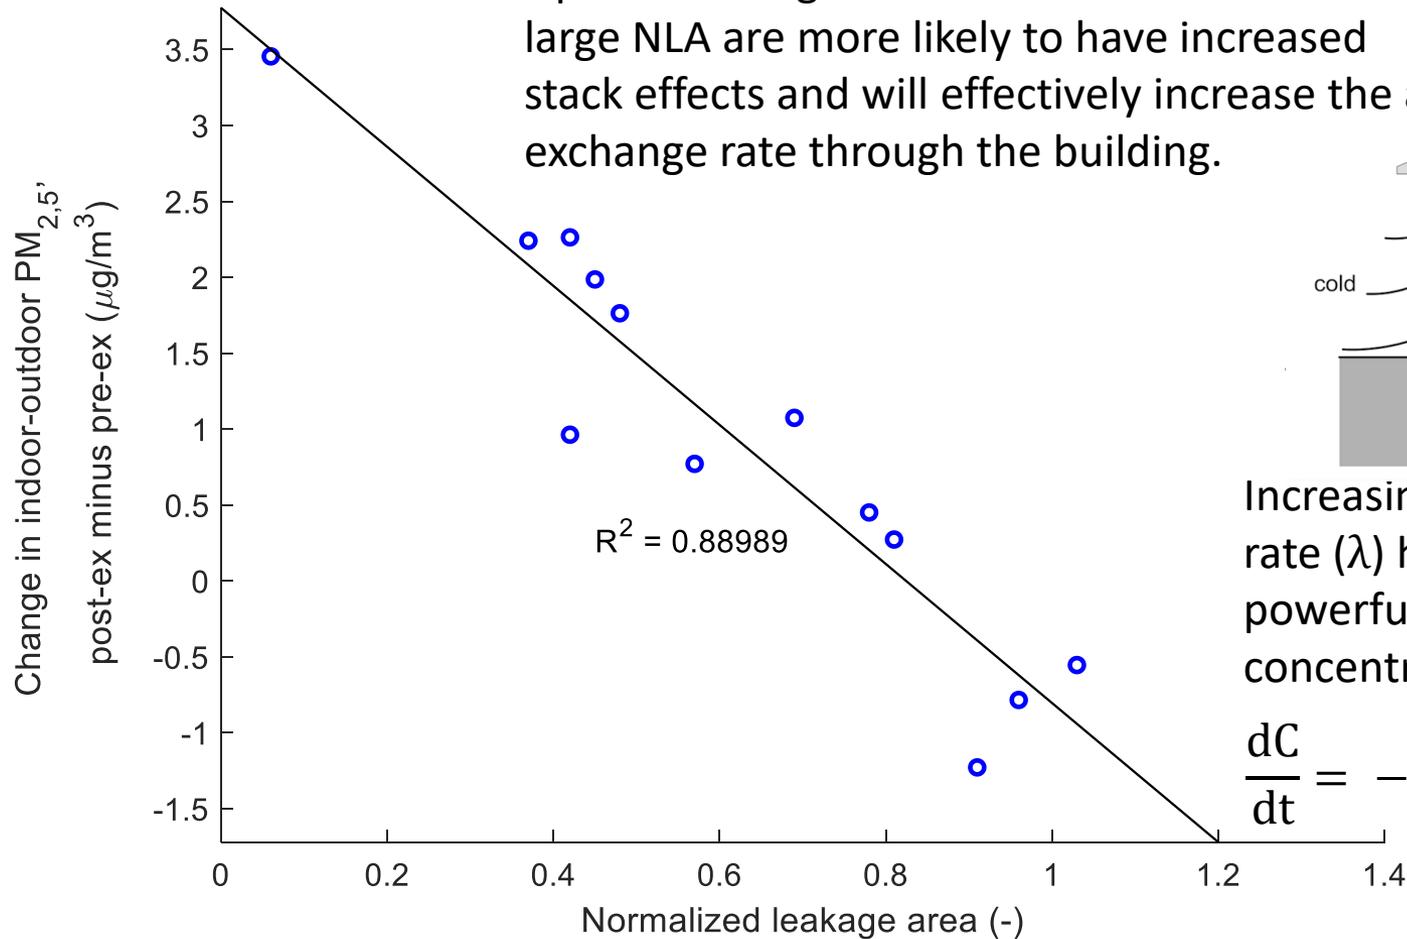

Correlation between normalized leakage area (NLA) and changes in PM_{2.5}

Correlation between normalized leakage area (NLA) and changes in PM_{2.5}

Upon receiving a new woodstove homes with a large NLA are more likely to have increased stack effects and will effectively increase the air exchange rate through the building.

Increasing the air exchange rate (λ) has a direct and powerful effect on indoor concentration of pollutants.

$$\frac{dC}{dt} = -\lambda C + \lambda C_{out} + S/V$$

Key Findings

- For 13 of 17 homes, large transient peaks of $PM_{2.5}$ were observed following the first stove use.
- Depending on method of comparison different number of homes showed a reduction in indoor $PM_{2.5}$
 - Including all data 7 homes showed reductions.
 - Excluding periods of stove inactivity, 12 homes showed reductions.
 - Excluding periods of stove inactivity and first burn peaks, 12 homes showed reductions.
- Differences in median $PM_{2.5}$ are not statistically significant
- Air tightness is anti-correlated with $\Delta C_{PM_{2.5}}$, implying homes with high ventilation removed indoor emissions from the woodstoves.
- For 4 homes studied, normal stove operation resulted in $PM_{2.5}$ source strengths on the magnitude of normal household activities.

Limitations

- Homeowner instrument interference resulted in data loss
- Short heating season limited number of homes participating and amount of data gathered.
- Loud machines dissuaded some homeowners from participating in the enhanced monitoring.

- Stove source strength analysis should continue across more homes.
- Since homeowner stove use habits can result in large emission events, a comparison of pre and post source strength could occur for each stove exchange.

Questions?

Blower door test (1/3)

Pressure-flow relationships were log transformed and plotted to determine the air leakage coefficient, C ($\text{m}^3/\text{s}/\text{Pa}^n$), and the pressure exponent, n (-), of each house from a least squares regression fit of the linearized equation below.

$$\log Q = \log C + n \log \Delta P$$

From this the typically reported metric, air changes per hour at 50 Pa was interpolated. This value is known as the ACH_{50} .

Appendix A: Blower door test (2/3)

- The estimated leakage area, ELA (m²) is the cross-sectional area of an orifice that would yield the same leakage flow rate as the building if subjected to a 4 Pa pressure difference.
- This value can be used in the Lawrence Berkeley National Laboratory infiltration model to estimate infiltration from the indoor-outdoor pressure difference or from environmental conditions like local wind speeds and indoor-outdoor temperature differences.
- The ELA value was calculated from the previously defined C and n and a reference pressure difference, P_r, of 4 Pa by using the equation below.

$$ELA = \sqrt{\frac{\rho}{2}} C \Delta P_r^{n-0.5}$$

Appendix A: Blower door test (3/3)

Normalized leakage (NL, -) was calculated from the effective leakage area, using the following equation developed by the Lawrence Berkeley National Laboratory and as described in ASHRAE Standard 119. H and Href are ceiling height and a reference height respectively.

$$NL = 1000 \times \left(\frac{ELA}{A_{\text{floor}}} \right) \left(\frac{H}{H_{\text{ref}}} \right)^{0.3}$$
